Diagnosing and Fixing Common Problems With Regression

Introduction

There are three ways to get a good intuitive grasp of whether there might be some issues with your model fit:

1. Plot the data
2. Plot the data
3. Plot the data

Collinearity

The test to use for collinearity in Stata is `vif`. The results of the VIF (Variance Inflation Factor) test states whether inflation has been increased because the covariate is correlated with the other regressors. The rule of thumb with VIF's is that 10 is large, while 20 is unacceptable.

Stata's vif command can be run after a regression to check for collinearity.

```
.
. estat vif

    Variable |       VIF       1/VIF
-------------+----------------------
          iq |     52.76    0.018955
       test3 |     52.24    0.019143
           s |      1.60    0.623911
         kww |      1.31    0.761735
         med |      1.18    0.848345
        expr |      1.15    0.867604
      tenure |      1.10    0.907839
         rns |      1.06    0.944157
        smsa |      1.05    0.948668
-------------+----------------------
    Mean VIF |     12.61
```

It looks like there's a big problem with the iq variable and the test3 variable. I first do an F test to see if they both belong in the model.

```
. test test3 iq

 ( 1)  test3 = 0
```

```
 ( 2)  iq = 0

       F(  2,   748) =    6.65
            Prob > F =    0.0014
```

They are jointly significant, so I need to choose one to eliminate. In this case I drop test3, re-run the model, and ask again for variance inflation factors.

```

    Mean VIF |      1.24
```

Much better! All vifs are now in an acceptable range.

Remember that as a practical matter, collinearity does not bias your estimates, it just makes them inefficient. It's usually just not that serious a problem— but it's worth checking to see if you're dealing with an extreme case.

Quick Exercise

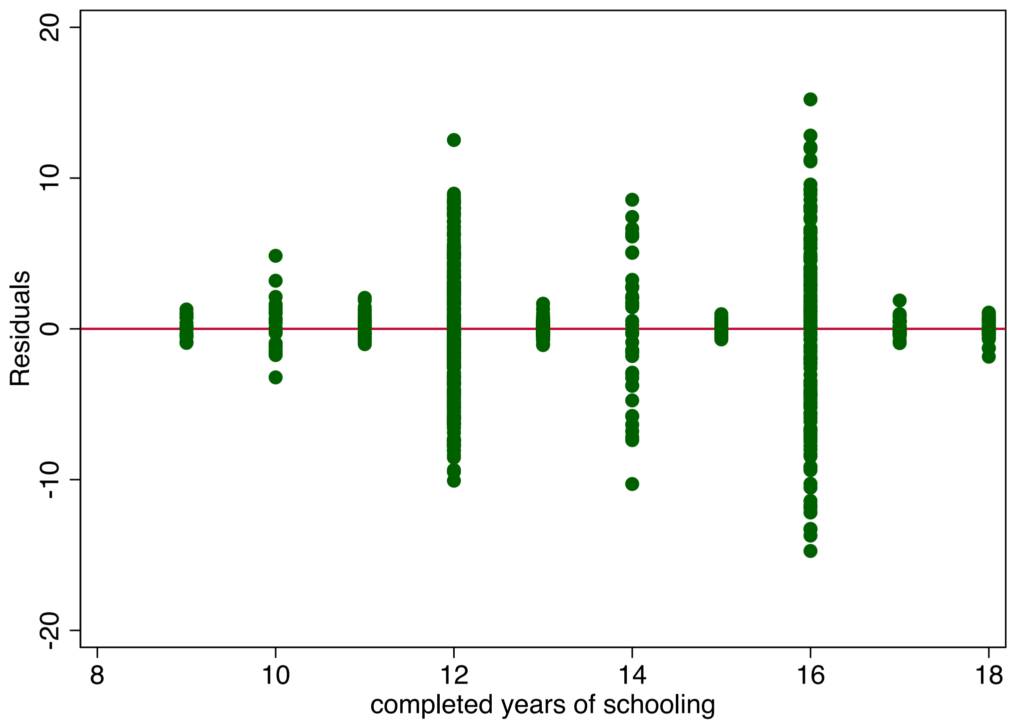
What happens to VIFs when a variable of your choice is removed?

Heteroskedasticity

Heteroskedasticity implies that the error terms are not identically distributed, but instead may be related in some way to the regressors or another factor. In this situation, our estimates are unbiased, but our distributional assumptions about our *variance* estimates no longer hold, and standard tests of significance don't work.

Figure 1 shows the residuals for a regression of log wages on various covariates plotted against years of experience. This shows a highly heteroskedastic pattern in the residuals.

Figure 1: Residuals Plotted Against Years of Experience



There are several ways of attempting to diagnose heteroskedastic results. The Breusch-Pagan command as an omnibus test looks at whether the variance of the squared residuals is related to any of the regressors.We get this by regressing the square of the residuals on the covariates and conducting an F test (or an LM test of the form nR^2). If significant, then the covariates predict the residuals, which indicatres a violation. In Stata we get this result by using the hettest command. Another option is the White test. The White test follows the same basic form as the BP test, but instead uses the test statistic nR^2 from the regression of the square of the residuals on the covariates, their squares, and their cross-products. Like the BP test, this test statistic has been shown to be distributed χ^2 with degrees of freedom equal to the number of regressors in the auxiliary regression.

```
Breusch-Pagan / Cook-Weisberg test for heteroskedasticity
         Ho: Constant variance
         Variables: fitted values of lw_het
```

```
        chi2(1)      =     4.69
        Prob > chi2  =   0.0304

.
. estat hettest s expr

Breusch-Pagan / Cook-Weisberg test for heteroskedasticity
        Ho: Constant variance
        Variables: s expr

        chi2(2)      =    21.50
        Prob > chi2  =   0.0000

.
. /*White Test */
.
. estat imtest, white

White´s test for Ho: homoskedasticity
        against Ha: unrestricted heteroskedasticity

        chi2(42)     =     87.39
        Prob > chi2  =    0.0000

Cameron & Trivedi´s decomposition of IM-test

---------------------------------------------------
              Source |       chi2     df      p
---------------------+-----------------------------
  Heteroskedasticity |      87.39     42    0.0000
            Skewness |       7.80      8    0.4534
            Kurtosis |      15.12      1    0.0001
---------------------+-----------------------------
               Total |     110.31     51    0.0000
---------------------------------------------------
```

In the first BP test above, the squared residuals are regressed on the predicted values from the regression. In the second test, the squared residuals are regressed on all of the covariates. And in the last, the squared residuals are regressed on a specified subset of the covariates. This last can help to identify the source of the non iid error terms.

You can correct for heteroskedasticity in a number of ways. The most straightforward is to use robust standard errors, which take into account possible non iid errors. If you suspect the errors in clusters (such as schools) are correlated, you can calculated clustered standard errors, with clustering at the group level. (N.B. My example below is artificial, and honestly, incorrect).

```
. /*Robust s.e.´s*/
. reg lw_het `x´ `controls´, robust

```

Angrist and Pischke suggest that we should assume that there IS heteroskedasticity in the residuals, unless we can specifically prove that there's none. Basically, you should always use robust standard errors (or other appropriate variance estimation technique).

Quick Exercise

Is there heteroskedasticity when we don't use the (made up) log wage variable, but rather the real one?

Data Scaling

The results of regression are invariant to linear transforms, but sensitive to non-linear transforms. Changing the latter changes the functional form of the regression model.

Results can be scaled in any number of ways. The most common is standardized coefficients, which scales each coefficient as follows:

$$\hat{\beta}_j^s = \hat{\beta}_j \frac{SD(x_j)}{SD(y)}$$

In the results below I show the standardized coefficients for the independent variables in the model, then transform the years of schooling variable and re-run the model. While the coefficient estimates change, the t-statistic and standardized coefficient does not.

```

Quick Exercise

Rescale the parental education variable using both a linear and a non-linear transform and check to see what difference it makes in the results.

Functional Form

In checking on functional form, your best bet is almost always using graphical approaches. Below I plot the wages as a function of years of schooling, then plot the a line based on local linear regression.

Figure 2: Wages as a function of schooling

Next I plot both a lowess line and a linear fit to see what the results of a simple regression might look like.

Figure 3: Wages as a function of schooling, linear fit to data

Figure 4: Wages as a function of schooling, multiple functional forms

Quick Exercise

Using a similar approach to the one I use in the do file, check on the functional form of the relationship between wages and kww scores.

The log transformation

TBD

Influential Observations

Regression is quite sensitive to outliers. A data point can "pull" the regression line quite far away given its distance from that line. We test for influential measures using several different measures including leverage, dfits, cooks D, or dfbeta.

- Leverage is measured in the scale of the dv and is the basic measure of influence from a residual.
- The dfits statistic compares the standardized residual for every observation on the scale of the standard error of the regression.
- Cook's d combines information regarding leverage—how influential the observation is on the results— and the size of the residual—how far off the prediction the actual result is.
- Dfbetas are calculated for every unit AND every coefficient, and state how far the coefficient would move should that case be excluded.

A leverage plot is a good place to being examining the data for influential observations.

Figure 5: Leverage Plot

The leverage plot shows the leverage of each observation on the y axis and the square of the residual on the x axis. The red lines on each axis are the cutoff points for "large" leverage or residual stats.

For each of the measures leverage, dfits, cooks' D and dfbeta, the procedure is the same. Calculate the measure, then look for observations that exceed a given rule of thumb. Here's that procedure applied to leverage.

For DFits, the measure is given by:

$$DFITS_j = r_j \sqrt{fraceh_j 1 - h_j}$$

Where r_j is a studentized residual:

$$r_j = \frac{\epsilon_j}{s_{(j)}} \sqrt{1 - h_j}$$

The rule of thumb cutoff for dfits is $|DFITS_j| > 2\sqrt{k/N}$.

For Cook's D, the calculation is:

$$D_i = \frac{\sum_{i=1}^{n} (\hat{y}_i - \hat{y}_{i(w)})^2}{pMSE}$$

Where $\hat{y}_i$ is the prediction with observation i and $\hat{y}_{i(w)}$ is the prediction *without* observation i.

The rule of thumb for cooks D is to investigate values over $4/n$.

Last, the calculation for DFBETA is given by:

$$DFBETA_j = \frac{r_j v_j}{\sqrt{v^2(1-h_j}}$$

This tells you how much a regression coefficient would change if unit j was excluded. The cutoff suggested for DFBETA is $2/\sqrt{n}$.

```

Quick Exercise

Run the same regression without the schooling variable. Check for outliers using both graphical and tabular methods.
